Conflicting Results Between Randomized Trials and Observational Studies on the Impact of Proton Pump Inhibitors on Cardiovascular Events When Coadministered With Dual Antiplatelet Therapy

Systematic Review

Chiara Melloni, MD, MHS; Jeffrey B. Washam, PharmD; W. Schuyler Jones, MD; Sharif A. Halim, MD; Victor Hasselblad, PhD; Stephanie B. Mayer, MD; Brooke L. Heidenfelder, PhD; Rowena J. Dolor, MD, MHS

Background—Discordant results have been reported on the effects of concomitant use of proton pump inhibitors (PPIs) and dual antiplatelet therapy (DAPT) for cardiovascular outcomes. We conducted a systematic review comparing the effectiveness and safety of concomitant use of PPIs and DAPT in the postdischarge treatment of unstable angina/non-ST-segment–elevation myocardial infarction patients.

Methods and Results—We searched for clinical studies in MEDLINE, EMBASE, and the Cochrane Database of Systematic Reviews, from 1995 to 2012. Reviewers screened and extracted data, assessed applicability and quality, and graded the strength of evidence. We performed meta-analyses of direct comparisons when outcomes and follow-up periods were comparable. Thirty-five studies were eligible. Five (4 randomized controlled trials and 1 observational) assessed the effect of omeprazole when added to DAPT; the other 30 (observational) assessed the effect of PPIs as a class when compared with no PPIs. Random-effects meta-analyses of the studies assessing PPIs as a class consistently reported higher event rates in patients receiving PPIs for various clinical outcomes at 1 year (composite ischemic end points, all-cause mortality, nonfatal MI, stroke, revascularization, and stent thrombosis). However, the results from randomized controlled trials evaluating omeprazole compared with placebo showed no difference in ischemic outcomes, despite a reduction in upper gastrointestinal bleeding with omeprazole.

Conclusions—Large, well-conducted observational studies of PPIs and randomized controlled trials of omeprazole seem to provide conflicting results for the effect of PPIs on cardiovascular outcomes when coadministered with DAPT. Prospective trials that directly compare pharmacodynamic parameters and clinical events among specific PPI agents in patients with unstable angina/non–ST-segment–elevation myocardial infarction treated with DAPT are warranted.

(Circ Cardiovasc Qual Outcomes. 2015;8:47-55. DOI: 10.1161/CIRCOUTCOMES.114.001177.)

Key Words: acute coronary syndrome ▪ proton pump inhibitors

Proton pump inhibitors (PPIs) are often prescribed together with antiplatelet therapy to prevent gastrointestinal complications, such as ulceration and bleeding. Clopidogrel, a potent antiplatelet used in the treatment of patients with coronary artery disease, is a prodrug that requires metabolic transformation in the liver by cytochrome P-450 isoenzyme (CYP2C19) to acquire its antiaggregation properties. PPIs are also metabolized by CYP enzymes, leading to a potential competitive inhibition of CYP2C19 and reduced activation of clopidogrel when used together.

Several pharmacodynamic studies have reported a significant decrease in the effect of clopidogrel on platelet aggregation when coadministered with omeprazole. These observations led the US Food and Drug Administration and the European Medicines Agency in 2009 to discourage the combination of clopidogrel and PPIs (in particular, omeprazole). Effects of concomitant administration on clinical outcomes have been discordant; some studies report an increased risk of major cardiovascular events whereas others report no difference.

We conducted this systematic review to evaluate the comparative effectiveness and safety of concomitant use of PPIs...
WHAT IS KNOWN

- A significant decrease in the effect of clopidogrel on platelet aggregation when coadministered with proton pump inhibitor (PPI) omeprazole has been reported in several pharmacodynamic studies. The clinical effect of the pharmacodynamic interaction between PPIs and clopidogrel remains unclear because results from observational studies have been discordant.
- The Food and Drug Administration and EMEA discourage the combination of clopidogrel and omeprazole.

WHAT THE STUDY ADDS

- Using a systematic review approach, we evaluated the effectiveness and safety of PPIs when coadministered with clopidogrel in unstable angina/non–ST-segment–elevation myocardial infarction population.
- Omeprazole was the only PPI studied in randomized controlled trials. Results from randomized controlled trials did not show increased risk of ischemic events when omeprazole was coadministered with clopidogrel.
- A systematic assessment of the data obtained from observation studies suggested increased risk of cardiovascular outcomes when PPIs (as a class) were coadministered with clopidogrel.
- Even models and propensity scores adopted in observational studies may have not fully addressed biases in patients selection. Overall, the systematic review of available evidence suggests the need of future randomized studies combining the assessment of pharmacodynamic parameters and their association with clinical outcomes.

Data Extraction and Quality Assessment

Two investigators independently reviewed titles, abstracts, and full-text articles for eligibility. We included original studies that were comparative assessments of strategies for treating patients with UA/NSTEMI with an indication for DAPT and who were discharged on PPIs. For this analysis, we excluded studies if (1) the populations were composed entirely of STEMI or stable angina patients, (2) the outcomes of interest were not reported, or (4) the studies were nonclinical (eg, editorial, letter to the editor, and case series).

One investigator abstracted data on general study characteristics, study population, eligibility criteria, treatment strategy, clinical outcomes, and safety using standardized forms. A second investigator over-read the abstraction to check for accuracy and completeness. We used predefined criteria to assess study quality using the summary ratings of good (low risk of bias), fair (moderate risk), or poor (high risk). To assess study applicability, we evaluated the study eligibility criteria, study population demographics, clinical relevance, and timing of the outcome measures.

Data Synthesis and Analysis

We synthesized the primary literature by continuous data (eg, age and event rates) and categorical data (eg, race/ethnicity). Feasibility of completing a quantitative synthesis (meta-analysis) was based on the range of confidence intervals (CIs) of the random-effects summaries. We considered meta-analysis for comparisons where ≥3 separate studies reported data for the same outcome at a similar time of follow-up. Meta-analyses were based on the nature of the outcome variable, random-effects models were used for all outcomes to accommodate the heterogeneity of the studies. Dichotomous outcome measures comparing 2 treatments were combined using hazard ratios (HRs) and random-effects model using Comprehensive Meta-Analysis version 2 software (Biostat; Englewood, NJ).

Some studies reported only standard-adjusted results, others only propensity-adjusted results, and some reported both. For each outcome evaluated, we first performed a meta-analysis comparing the data types of estimates and looked for potential differences. As a second step, we did a meta-analysis using the propensity-adjusted HR (P) when it was available and the standard-adjusted HR (A) when the propensity-adjusted ratio was not available. We tested for statistical heterogeneity between studies (Q and F statistics) while recognizing that the power to detect such heterogeneity may be limited. Potential heterogeneity between studies was determined by evaluating the range of confidence intervals (CIs) of the random-effects summary statistics.

We assessed the strength of evidence using the 4 required domains: risk of bias, consistency, directness, and precision. We graded the strength of evidence for each outcome; thus, a given study may be of different quality for 2 individual outcomes reported within that study. The studies were evaluated for the presence of confounders that would diminish an observed effect, strength of association (magnitude of effect), and publication bias. These domains were considered qualitatively, and a summary rating of high, moderate, or low strength of evidence was assigned.

Results

Thirty-five studies (4 randomized controlled trials [RCTs] and 31 observational) assessed the effect of antiplatelet therapy coadministered with PPI compared with DAPT alone (ie, no PPI) in the postdischarge treatment of patients with UA/NSTEMI (Appendix Table I in the Data Supplement). Four studies, consisting of 3 RCTs and 1 observational study in 5183 patients with UA/NSTEMI, assessed the effect of omeprazole added to DAPT; and 1 RCT comparedesomeprazole with famotidine for the prevention of gastrointestinal bleeding. The other 30 studies, all observational, assessed the

and dual antiplatelet therapy (DAPT) among patients with unstable angina/non–ST-segment–elevation myocardial infarction (UA/NSTEMI).

Methods

This analysis was part of a broader systematic review assessing the effectiveness and safety of antiplatelet and anticoagulant medications used to treat patients with UA/NSTEMI. The full evidence report contains a detailed description of the methods and results, including evidence tables.

Study Selection

We searched for clinical studies in MEDLINE, EMBASE, and the Cochrane Database of Systematic Reviews, from January 1, 1995, to July 30, 2012. We also searched the gray literature of study registries and conference abstracts for relevant articles from completed trials and reviewed reference lists of relevant review articles to provide additional citations. Figure 1 depicts the flow of articles through the literature search and screening process.
effect of PPIs as a class compared with no PPI in the setting of DAPT. The summary results and strength of evidence ratings are shown in the Table.

**Effect on Composite Ischemic End Point at ≈1 Year**

The RCT comparing omeprazole with famotidine reported a nonsignificant difference in the rate of composite outcomes (cardiovascular mortality, nonfatal MI, or stroke) at 4 months between the 2 groups (4.3% versus 3.4%; \(P=0.7788\)). Another RCT comparing omeprazole with placebo reported a nonsignificant difference in the rate of composite outcomes (cardiovascular mortality, nonfatal MI, stroke, or revascularization) at 6 months between the 2 arms (4.9% versus 5.7%; HR, 0.99; 95% CI, 0.68–1.44; \(P=0.96\)). Similarly, an observational study comparing omeprazole versus no omeprazole reported a nonsignificant difference in the rate of composite outcomes (cardiovascular mortality or nonfatal MI) at 12 months between the 2 groups (10% versus 9.7%; unadjusted HR, 1.1; 95% CI, 0.6–1.8; \(P=0.89\)).

Twenty observational studies reported the effect of any PPI on the composite end point of all-cause mortality, stroke, or MI at 6 to 18 months. Ten reported only standard-adjusted results, 3 only propensity-adjusted results, and 7 reported both. The overall estimate for the standard-adjusted HRs was 1.40, whereas the overall estimate for the propensity-adjusted HRs was 1.34 (\(\chi^2=0.111\) for 1 degree of freedom; \(P=0.739\)). Figure 2A shows the propensity-adjusted HR (P) when it was available and the standard-adjusted HR (A) when the propensity-adjusted HR was not available. The random-effects combined estimate was 1.35 (95% CI, 1.18–1.54; \(P<0.001\); low-strength evidence).

**Effect on Composite End Point of All-Cause Mortality or Nonfatal MI at ≈1 Year**

Three observational studies with 60,389 patients reported the effect of any PPI on all-cause mortality or MI at 6 to 18 months. One reported only standard-adjusted results, and 2 reported both standard and propensity-adjusted results. The overall estimate for the standard-adjusted HRs was 1.23, the estimate for the propensity-adjusted HRs was 1.31 (\(\chi^2=0.265\) for 1 degree of freedom; \(P=0.607\)). Figure 2B shows that the random-effects combined estimate was 1.27 (95% CI, 1.12–1.43; \(P<0.001\); moderate-strength evidence).

**Effect on All-Cause Mortality at ≈1 Year**

Three studies of omeprazole (2 RCTs and 1 observational) reported all-cause or cardiovascular mortality within at 6 to 18 months. One RCT comparing omeprazole with placebo in 237 patients with acute MI reported a significant difference in all-cause mortality at 14 days favoring omeprazole (3.5% versus 10.6%; \(P=0.035\)). One RCT comparing omeprazole with placebo in a mixed population of 3873 acute coronary syndrome and percutaneous coronary intervention (PCI) patients reported a nonsignificant difference in all-cause mortality at 6 months between omeprazole and placebo (4% versus 5%). Similarly, an observational study comparing omeprazole versus no omeprazole in a mixed population of 558 stable angina and patients with acute coronary syndrome reported a nonsignificant difference in cardiovascular mortality at 1 year between omeprazole and placebo (3.5% versus 3.2%; unadjusted HR, 1.10; 95% CI, 0.44–2.84; \(P=0.84\)).

Of the 17 observational studies that reported the effect of any PPI on all-cause mortality at 6 to 18 months, 11 reported only standard-adjusted results, 2 only propensity-adjusted results, and 4

†HRs <1 favor PPI use; ORs >1 favor no PPI use.

reported both. The overall estimates for the standard-adjusted HRs and propensity-adjusted HRs were 1.18 and 1.44, respectively (χ²=1.271 for 1 degree of freedom; P=0.258). Figure 2C shows that the random-effects combined estimate was 1.17 (95% CI, 0.92–1.48; P=0.20; moderate-strength evidence).

Effect on Nonfatal MI at ≈1 Year

Two studies (1 RCT and 1 observational) of omeprazole reported nonfatal MI within the first year. The RCT found a nonsignificant reduction of nonfatal MI at 6 months (1.2% versus 1.5%; HR, 0.92; 95% CI, 0.44–1.90; P=0.81) with omeprazole. Similarly, the observational study found no effect of omeprazole versus no omeprazole on nonfatal MI (6.5% versus 6.5%; HR, 1.0; 95% CI, 0.5–1.9).

Ten observational studies reported the effect of any PPI use on nonfatal MI at 6 to 18 months. 5,9,17,18,23,27,31,35,41,42 Six
reported only standard-adjusted results, 3 both standard and propensity-adjusted results, and 1 reported only propensity-adjusted results. The overall estimate for the standard-adjusted and propensity-adjusted HRs was 1.35 and 1.33, respectively (χ²=0.005 for 1 degree of freedom; P=0.941). Figure 2D shows that the random-effects combined estimate was 1.33 (95% CI, 1.15–1.55; P<0.001; low-strength evidence).

Effect on Stroke at 30 Days and at ≈1 Year
Nonsignificant differences were found in the rate of both transient ischemic attacks at 30 days (2.3% versus 1.0%)13 and stroke events at 6 months (stroke 0.2% versus 0.3%)15 between patients treated with omeprazole compared with those receiving placebo. Five observational studies reported the effect of any PPI on stroke at 6 to 18 months.17,18,27,32,42 Four reported only standard-adjusted results, and one reported both standard and propensity-adjusted results. Figure 2E shows that the random-effects combined estimate was 1.49 (95% CI, 1.20–1.84; P<0.001; low-strength evidence).

Effect on Revascularization at ≈1 Year
One RCT15 found a similar rate of revascularization at 6 months among patients discharged on omeprazole compared with those discharged without (4.0% versus 4.6%). One observational study31 similarly found no difference in the risk of revascularization at 6 months among 22,326 patients with UA/NSTEMI treated with omeprazole compared with those not treated with PPI (adjusted HR, 0.97; 95% CI, 0.79–1.21; low-strength evidence).

One observational study44 found a similar rate of revascularization at 1 year for 588 patients with UA/NSTEMI discharged on omeprazole compared with those discharged without omeprazole (9.4% versus 8.9%).

A random-effects meta-analysis of 4 observational studies of any PPI,8,11,27,30 including 52,576 patients with UA/NSTEMI assessing revascularization at 1 year reported standard-adjusted results, and 1 study additionally reported propensity-adjusted results.13 Figure 2F shows that the random-effects combined estimate was 1.48 (95% CI, 1.21–1.82; low-strength evidence). There was evidence of heterogeneity that seemed to be because of the Banerjee study.13 As a sensitivity analysis, we performed a meta-analysis where we used only the adjusted HR from the Banerjee study.13 One RCT15 found a similar rate of revascularization at 6 months among patients with UA/NSTEMI treated with or without PPI (3.5% versus 3.8%; HR, 0.97; 95% CI, 0.79–1.21; low-strength evidence). The other15 reported stent thrombosis (definite, possible, and probable) at 6 months among patients treated with PPI versus placebo (9.4% versus 8.9%; P=0.65). Given the differences in the duration of follow-up both in the RCTs and observational studies, a meta-analysis was not performed; however, there is moderate-strength evidence that favors use of PPIs for reducing gastrointestinal bleeding.

Effect on Stent Thrombosis at ≈1 Year
Two studies (1 RCT and 1 observational) of omeprazole reported stent thrombosis (definite, possible, and probable) within 1 year. In the RCT,15 2 cases of definite or probable stent thrombosis occurred at 6 months in the placebo group, and no cases occurred in the omeprazole group. A nonsignificant difference in stent thrombosis was found among patients discharged on omeprazole compared with those discharged without (8.8% versus 5.8%; HR, 1.1; 95% CI, 0.7–1.8) at 1 year in the observational study.44

Six observational studies reported the effect of any PPI use on stent thrombosis at 6 to 18 months.5,23,25,34,35,39 Four reported only standard-adjusted results, and 2 only propensity-adjusted results. The overall estimate for the standard-adjusted and for propensity-adjusted HRs was 1.35 and 1.33, respectively (χ²=0.005 for 1 degree of freedom; P=0.941).15,21,28,33 Figure 2G shows that the random-effects combined estimate was 1.34 (95% CI, 1.17–1.55; P<0.001; low-strength evidence).

Effect on Gastrointestinal Bleeding
Four RCTs of omeprazole reported gastrointestinal bleeding.15,21,28,33 Three found that the use of omeprazole significantly reduced the rates of upper gastrointestinal bleeding at 14 days and at 4 and 6 months.

Four observational studies of any PPIs reported on gastrointestinal bleeding.14,19,29,32 One14 found no difference in the rate of in-hospital gastrointestinal bleeding between patients discharged with and without PPI (0.7% versus 0.6%; P=0.88). Another32 found a significant increase in the rate of in-hospital gastrointestinal bleeding among patients not receiving PPI compared with those treated with PPI (4.8% versus 0.6%; P=0.001). The 2 studies reporting gastrointestinal events at longer follow-up found dissimilar results. One32 found no differences in gastrointestinal bleeding at 18 months between patients with UA/NSTEMI treated with or without PPI (3.5% versus 3.8%; HR, 0.97; 95% CI, 0.79–1.21; low-strength evidence). The other15 reported stent thrombosis occurred at 6 months in the placebo group, and no cases occurred in the omeprazole group. A nonsignificant difference in stent thrombosis was found among patients discharged on omeprazole compared with those discharged without (9.4% versus 8.9%; P=0.65). Given the differences in the duration of follow-up both in the RCTs and observational studies, a meta-analysis was not performed; however, there is moderate-strength evidence that favors use of PPIs for reducing gastrointestinal bleeding.

Discussion
Using a systematic review approach, we found that among patients with UA/NSTEMI with an indication for DAPT, the concomitant administration of PPIs (as a class) was associated with worse clinical outcomes in observational studies; however, 4 RCTs of omeprazole versus placebo report no difference in ischemic outcomes despite reducing upper gastrointestinal bleeding with omeprazole administration.

Several studies assessing platelet aggregation inhibition have shown how PPIs may significantly reduce the antiplatelet effect of clopidogrel when the 2 drugs are coadministered.2–5 This effect is attributed to an important pharmacokinetic interaction between the 2 drugs, where clopidogrel needs metabolic transformation to its active form by CYP2C19 enzyme, and PPIs inhibit this enzyme to different extents.

The findings from pharmacodynamic studies have not fully translated into a difference in clinical outcomes because multiple studies exploring the effect of concomitant use of PPIs and clopidogrel on major cardiovascular outcomes have found contrasting results.5,9,45,46

In our analysis of the use of PPIs with DAPT, we identified 35 studies, of which only 4 were RCTs. All RCTs investigating the effect of omeprazole compared with placebo or esomeprazole compared with famotidine (1 study) on cardiovascular outcomes showed no difference in ischemic events. The use of omeprazole...
Figure 2. Meta-analyses of dual antiplatelet therapy with and without proton pump inhibitor (PPI). A, Composite end point at about 1 year. Q=196.64 for 19 degrees of freedom (P<0.001), I²=93.34; indicate very significant heterogeneity. B, All-cause mortality and nonfatal myocardial infarction at about 1 year. Q=0.466 for 2 degrees of freedom (P=0.792), I²=0.00; indicate no heterogeneity. C, All-cause mortality at ≥1 year. ![Figure 2](http://circoutcomes.ahajournals.org/)

...continued...
medication suggest that event rates are higher in patients who receive any type of PPI medication for the composite outcome (all-cause mortality or nonfatal MI) at 1 year, and nonfatal MI, all-cause mortality, and revascularization after 1 year.

The potential for selection bias in observational trials is not negligible. Sicker patients, with more comorbidities and at higher baseline risk for adverse outcomes, are preferentially treated with PPI therapy, and as a result this cohort seems to have more adverse clinical outcomes. In an attempt to account for some of these baseline differences between patients who received PPI and those who did not, we used the results for standard and propensity score–matched HRs for each study. Also, when possible, we ran separate meta-analyses to assess the effect of adjustment on the clinical outcomes. For a majority of analyses, there was no statistically significant difference in the summary estimate for the standard-adjustment compared with the propensity-adjusted HRs. Many of the meta-analyses showed evidence of heterogeneity that is likely because of the variation in the clinical factors used to calculate the standard and propensity-adjusted HRs. The summary estimates for the standard/propensity-adjusted results showed HRs that were closer to 1, but for many outcomes the summary estimate still favored the no PPI group.

Aside from the underlying differences in patients’ baseline characteristics and comorbidities that were observed in the analysis population of the observational studies, there are other important factors to consider when comparing results from RCTs and observational studies. Among them, we found that observational studies lacked information on the PPI regimen, such as the dose and frequency of administration, the duration of treatment, concomitant medications, new prescription versus chronic therapy, and patients’ medication adherence.

Although we attempted to control for some of these confounding factors inherent to patient and clinical characteristics, it is highly probable that unmeasurable confounding still remains, and the effect of PPIs analyzed as a class in this analysis is not based on strong evidence. It is also unclear whether genetic resistance to clopidogrel is a causal factor, or whether the negative interaction may be drug specific or class specific. Those variables were not included in the studies we reviewed. The overall strength of evidence rating was downgraded because the findings from observational studies on PPI as a class conflicted with the few RCTs of omeprazole.

Study type and method of analysis can explain some variation in the relative hazard associated with the coadministration of PPI with clopidogrel; the risk of error is mitigated as the methodological rigor increases.

A recent update of the American Heart Association/American College of Cardiology guidelines has removed the recommendation to administer PPI to patients with a history of gastrointestinal bleeding, and in its place suggests that healthcare providers evaluate the need for starting or continuing PPI treatment in patients taking clopidogrel. Their statement does not prohibit the use of PPIs in appropriate clinical settings; however, they describe the potential risks and benefits from PPIs in combination with clopidogrel. Our findings also support a cautious approach to PPI use with DAPT therapy in patients with UA/NSTEMI.

Further research—preferably additional RCTs of specific PPI agents or prospective propensity score–matched cohort studies—is warranted on whether the detrimental effect of PPIs is because of comorbid conditions of the patient population, to the specific PPI agent used, or to genetic predisposition for reduced clopidogrel responsiveness.

Strengths and Limitations
Some considerations should be taken into account while interpreting these data. The strength of this review is its focus on comparative studies of antiplatelet and anticoagulant treatments; any studies that reported noncomparative findings were excluded. To review adequate numbers of studies to address the safety and effectiveness of PPIs when coadministered with DAPT in patients with UA/NSTEMI, we had to broaden our eligible patient population to include studies of either UA/NSTEMI or acute coronary syndrome (STEMI, NSTEMI, and unstable angina). Also, some PPI studies included patients with acute coronary syndrome or stable angina. To improve the applicability of our findings to the UA/NSTEMI population, we did exclude studies that focused exclusively on the STEMI or stable angina population.

In addition, different composite end point definitions made quantitative analysis less feasible. Information on adherence to clopidogrel or PPI treatment, dose of PPI, or switching between one PPI and another was not available. Finally, an analysis of the net benefit was not conducted (ie, assessing the effectiveness while accounting for the risk of these therapies).

Conclusions
Although the use of PPIs as a class was associated with worse clinical outcomes in observational studies of patients with UA/NSTEMI receiving DAPT, the results from a small number of RCTs of omeprazole showed no significant difference in clinical events. Prospective trials directly comparing pharmacodynamic parameters and clinical events of different PPIs in patients with UA/NSTEMI treated with DAPT are warranted.

Acknowledgments
We thank Dr. Kato, Agency for Healthcare Research and Quality Task Order Officer and Dr. Bass for their suggestions on improving the clarity of the report; Megan von Isenburg, MSLS, for help with the literature search and retrieval; R. Julian Irvine, MCM, for project coordination; and Liz Wing, MA, for editorial assistance. The authors of this report are responsible for its contents; particularly, Dr Melloni had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. Drs Melloni and Dolor helped in concept and design. Drs Melloni, Dolor, and Hasselblad helped in acquisition of data. Drs Melloni, Dolor, and Hasselblad helped in analysis and interpretation of data. Dr Melloni helped in drafting of the article. Dr Dolor, J.B. Washam, Dr Mayer, and Dr Jones helped in critical revision of the article for important intellectual content. Drs Hasselblad and Dolor helped in statistical analysis. Dr Heidenfelder helped in provision of study materials. Dr Dolor helped in obtaining funding. Dr Heidenfelder helped in administrative, technical, or logistic support. Dr Dolor helped in supervision.
Sources of Funding
This study received funding from the Agency for Healthcare Research and Quality, US Department of Health and Human Services (contract No. 290-2007-10066-I). Statements in the report should not be construed as endorsements by the Agency for Healthcare Research and Quality or the US Department of Health and Human Services. The Agency for Healthcare Research and Quality reviewed the work plan before the project began and provided copyright release for this article. Neither the technical experts nor the Agency for Healthcare Research and Quality representatives had a role in the collection, management, analysis, and interpretation of the data or preparation, review, or approval of the article.

Disclosures
Dr Jones reports research grants to the Duke Clinical Research Institute and the American College of Physicians. The Dr Mayer reports research grants from NIH T32DK070012 Endocrinology and Metabolism Research Training Program.

In the article by Melloni et al, “Conflicting Results Between Randomized Trials and Observational Studies on the Impact of Proton Pump Inhibitors on Cardiovascular Events When Coadministered With Dual Antiplatelet Therapy: Systematic Review,” which initially published online January 13, 2015 and which appeared in the January 2015 issue of the journal (Circ Cardiovasc Qual Outcomes. 2015;8:47–55. doi: 10.1161/CIRCOUTCOMES.114.001177), a correction to the Disclosures section is needed; additional funding needed to be reported.

The original text read:

“Dr Jones reports research grants to the Duke Clinical Research Institute from the American Heart Association, AstraZeneca and Bristol-Myers Squibb, and consultant/honoraria from the American Physician Institute and the American College of Physicians. The other authors report no conflicts.”

It should read:

“Dr Jones reports research grants to the Duke Clinical Research Institute from the American Heart Association, AstraZeneca and Bristol-Myers Squibb, and consultant/honoraria from the American Physician Institute and the American College of Physicians. Dr Mayer reports grant funding from NIH T32 grant (NIH 5T32DK007012 Endocrinology and Metabolism Research Training Program).”

The correction has been made to the final version of the article, which is available at http://circoutcomes.ahajournals.org/content/8/1/47.

The authors regret the error.
